INDIAN INSTITUTE OF TECHNOLOGY MADRAS Department of Chemical Engineering

CH3050 Process Dynamics and Control

Assignment #4

Due: Saturday, March 22, 2020

Exercises

- 1. Consider a process whose transfer function is given by $G(s) = \frac{(s+0.5)e^{-3s}}{(20s+1)(10s+1)(5s+1)(s+1)}.$
 - (a) Simulate the step response of this system and fit an FOPTD model using Krishnaswamy and Sundaresan's method (of two points)
 - (b) From the transfer function, directly obtain the FOPTD and SOPTD approximations using Skogestad's half-rule method
 - (c) Fit an SOPTD model using the frequency-domain (magnitude and phase) least-squares approximation method.
 - (d) Compare the step responses of the models obtained in parts (a)-(c) with that of the original one. Tabulate your observations.
- 2. It is desired to develop an empirical model for a process. The exercise will provide insights into the data generation and subsequent model identification.
 - (a) Assume that the process is $G(s)=\frac{2(-0.5s+1)e^{-0.4s}}{(5s+1)(s+1)}$. Set up the SIMULINK diagram for the sampled-data system consisting of a ZOH, the process and the sampler in series. Choose $T_s=0.2$ s.
 - (b) Design the discrete-time input as a pseudo-random binary signal (PRBS). Use the idinput routine for this purpose. Generate N=2555 long sequence with B=0.2. Simulate the process using this input to the ZOH. Add measurement noise (of variance 0.1) at the output to obtain the measurement y[k]. Partition the data into **training** and **test** data sets.

[For the remainder of this exercise, you shall assume that no process knowledge is available.]

(c) A key first step is the estimation of delay. For this purpose, fit an FIR model,

$$y[k] \approx \sum_{n=0}^{M} g[n]u[k-n]$$

to the **training** data using the MATLAB routine impulseest. Examine the IR coefficient estimates to infer the delay (of the sampled-data system).

- (d) Estimate the step response using the step routine. From the obtained response, estimate the gain and make reasonable inferences of the order and/or any other process characteristics.
- (e) Next assume an appropriate model for the system,

$$y^{*}[k] + \sum_{i=1}^{n} a_{i}y^{*}[k-i] = \sum_{j=d}^{m} b_{j}u[k-j]$$
(1)

where the values of d, m and n have to be chosen as per your analysis of impulse and step responses (you are **not allowed** to use any knowledge of the process). Assuming white-noise errors in the measurements, estimate the parameters of (1) using the oe routine.

- (f) Assess the goodness of the model estimated in (2e) for underfit using the residual analysis. Use the resid routine for this purpose. Is the model satisfactory? If no, refine the model structure (by increasing the output and/or input orders) until the model passes this test satisfactorily. Subsequently, examine the errors in parameter estimates (using the present routine) and compare the gains of this model and the one obtained in (2d).
- (g) Report the final discrete-time model after cross-validation with the test data.
